1. INTRODUCTION

1.1 General

Offshore pipelines transport enormous quantities of oil and gas vital to the economies of virtually all nations. Any failure to ensure safe and continuous operation of these pipelines can have serious economic implications and possibly damage to the environment and cause fatalities. A prerequisite to pipeline safe operation is to ensure their structural integrity to a high level of reliability throughout their operational lives. Such integrity may be threatened by defects introduced into a pipeline system during its construction or operation. Since it is virtually impossible to prevent such defects from occurring and because not all defects are harmful to pipeline integrity, it is essential to be able to distinguish defects which can be tolerated from those which can not.

A large number of empirical and/or analytical tools for the assessment of pipeline defects are available. The project Appraisal and Development of Pipeline Defect Assessment Methodologies is to evaluate thoroughly all available methods for assessing offshore pipeline defects. The objective of this project is to establish a firm basis on all the major aspects of the methodology needed to assess the safety of offshore pipelines with geometric and material defects. Furthermore, it performs the necessary development to cover the remaining gaps in the state-of-the-art.

Based on the project proposal, the main tasks in the Phase 1 is the collation of pipeline defect related literature, including all available codes, standards, published reports and published papers. From the review of collated documents and interviews with Operators, a critical appraisal of current industry practice and code provisions would be undertaken. A database of screened test results for different defect forms would be created, and present-day inspection methodologies of offshore pipeline defects would be established.

This report represents a review of the progress of the project in Phase 1 of the above mentioned four aspects: Collation of pipeline defect related literature, Current industry practice, Code provisions, and Database of test results for different pipeline defect forms.

1.2 Background

A number of studies on the failure/loss of containment of pipelines have been conducted. Based on statistical analysis of information usually held by Regulatory Authorities and/or Pipeline Operators, these studies provide indications of the level of reliability achieved in the operation of pipelines. They also provide information on the likely level of failure frequency for an individual pipeline depending on factors such as:

- Cause of Failure
- Location of Pipeline

- Diameter of Pipeline
- Length of Pipeline
- Contents of Pipeline.

The most recent published studies on pipeline failures are as follows:

- Mandke evaluation of failure rate data for Gulf of Mexico using the US office of Minerals and Management Service (MMS) database. This covered 690 incidents that occurred during the Period 1967-87. Information from 1987- onwards is currently not available.
- HSE/UKOOA commissioned a number of studies of pipeline failures in the North Sea. Some results of the study are reported by Williams et al covering the period up to 1989. Further reports covering periods 1989 to 1992, and 1992 to 1994 have been released by the HSE (PARLOC) and findings 1994 to 1996 are due to be released shortly by the HSE.
- The Office of Pipeline Safety (OPS) of US Department of Transport (DOT) collected all pipeline incident data from 1968-1999.

Comparison of Gulf of Mexico (Mandke) and North Sea Pipeline failure studies indicated that the primary cause of failures listed in decreasing frequency of occurrence/detection were as follows:

Gulf of Mexico:

Corrosion, third party, storm and slides, material and

equipment failure.

North Sea:

Third Party, corrosion, material failure.

Data extracted from the Office of Pipeline Safety Database on incident and accident statistics for the period covering 1984-1999 is presented in Table 1.1 for hazardous liquids and Gas transportation/Distribution. It can be observed from Table 1.1 that the number of incidents and number of accidents etc are generally similar with no apparent decrease with time being noted. The primary cause for the incidents are presented in Tables 1.2 to 1.4. The tables indicate that the cause of damage resulted from a number of causes including the following:

- Corrosion (internal and external)
- Damage from outside forces (i.e mechanical damage)
- Defective weld and pipe
- Construction/material

The primary cause of failure listed in decreasing frequency of occurrence in general appears to be as follows:

• Damage from outside forces/outside damage, Corrosion (internal and external), defective pipe/weld.

Although the above information is incomplete and further information (eg. MMS Hurricane Andrew, HSE PARLOC updates) is to be considered, it can be observed that damage which require defect assessment procedures to be considered are required.

2. PROJECT STATUS

2.1 <u>Progress</u>

The project began in April 1999 with the execution of Phase I (Phase II is presently an option item). Phase I is split into two sub-items as follows:

ItemDescription0001ACreation of Database0001BCreation of Final Report

Phase I is to be completed within a 6 month timeframe. Various activities required to complete the scope of work were identified in MSL fax of February 17, 1999. These activities are listed below and a statement on progress is given for each.

a) Collate all available, pertinent, documents worldwide.

Approximately 400 references have been identified, of which 350 have been sourced. This number of references is at the upper end of expectations.

b) Undertake selective interviews in USA and UK.

Some thought has been given to the organisations that we would wish to interview, although none have yet been conducted. The interviews have been deliberately timed so that best use of them can be made, when data and experience gained from the references has been assimilated. An initial contact letter has been drafted, see Appendix, to facilitate arrangements for interviews. Since the letter makes reference to MMS, MMS may wish to review it.

c) Appraisal of documents and create database.

The source documents have been reviewed, see Section 3. A database has been established of test and numerical data for pipelines containing defects, see Section 6.

d) Critically appraise current industry practice.

Work has commenced on this activity with an examination of the various provisions of relevant codes. A summary is provided in Sections 4 and 5. This activity is to be enhanced with findings from the forthcoming interviews.

e) Establish present-day inspection methodologies.

Source documents containing references to inspection methodologies have been noted. However, this activity is yet to commence in earnest.

f) Preparation of final report.

This activity is yet to commence.

In summary, the project is on schedule and we expect to complete the study by the end of September 1999, ie. within the allocated Phase I period.

2.2 <u>Activities Planned for Next Quarter</u>

Phase I is expected to finish during the next quarter and therefore the planned activities are all those required to complete the scope of work. The remaining activities are:

- Source the 50 remaining references, extract the data, enter in the database and conduct QA checks on the entered data.
- Undertake interviews.
- Complete the appraisal of industry practice following the interviews.
- Document the inspection methodologies.
- Prepare final report.

2.3 <u>Information Requested from MMS</u>

We would appreciate an early response from MMS on whether the first contact letter (set out in the Appendix) is suitable or requires adjustment.

Furthermore, it is almost inevitable that interviewees will ask whether they would receive anything in return for supply of data. Advice is sought from MMS on a suitable response to this question.

3. LITERATURE CAPTURE

3.1 Methodology

The basic literature survey is the main task conducted in phase I of this project. There is a significant amount of literature on pipeline defect assessment. The literature search was performed in three categories. Category I includes codes and standards on offshore pipeline design and defects assessment. Category II includes all the technical papers relevant to defect assessment methodologies. Category III collects all the possible technical reports from governments and companies. The most popular and used codes and standards from different countries are also collected.

A literature database from all the collected codes, standards, technical papers from conference proceedings or journals was created which includes 400 references. Most of these references have been obtained although a small % (ie. approximately 12%) are still being sourced at the present moment. It is possible that the final number of references may be higher if new information is identified during the course of the project.

For each reference identified the following information has been recorded. Reference number, Title of paper, Author(s), organisation, date of publication, document reference (ie. conference, code, etc.).

In addition to this to enable searching of the database to be undertaken more efficiently, particularly in identifying those references which contain defect data, a number of key words have been identified (eg. defect assessment, code, corrosion damage, mechanical damage, weld damage, material, inspection, etc.). These key words are currently being further evaluated for future use in enabling interrogation of the database to be carried out more efficiently.

In this project, the emphasis was confined to offshore pipeline defect assessment and in particular to identifying those types of defect damage which commonly occur.

3.1.1 Definition of Defects

A defect is an imperfection of sufficient magnitude to warrant rejection based on the requirements of the codes or standards. An imperfection is a material discontinuity or irregularity that is detectable by inspection in accordance with the requirements of the codes and standards. Different codes and standards give different warranty of rejection of the defects. This will be explored in more detail when undertaking interviews and reviewing inspection methodologies.

3.1.2 Type of Defects

Pipeline defects can be grouped into three categories according to their cause. Mechanical damage, weld defect and corrosion defect can be defined as follows:

Mechanical Damage:

Dent: A depression caused by an event that produces a visible disturbance in the curvature of the wall of the pipe or component without reducing the wall thickness.

Gouge: A surface imperfection caused by mechanical removal or displacement of metal that reduces the wall thickness of a pipe or component.

Groove: Groove can cause stress concentration at the point and can be considered as a defect.

Surface Cracks: Pipe body surface cracks shall be considered defects.

Weld Defects:

Arc Burn: A localized condition or deposit that is caused by an electric arc and consists of remelted metal, heat-affected metal, a change in the surface profile, or a combination thereof.

Incomplete Penetration: The root head of weld does not completely fill the root of the joint.

Incomplete Fusion: There is lack of bond between the weld metal and the base metal at the root or top of the joint.

Internal Concavity: Incomplete filling of the joint.

Undercut: A groove melted into the base metal adjacent to a weld toe at the root or top of the joint.

Slag Inclusions: Non-metallic solid entrapped in the weld metal or between the weld metal and the base metal.

Hollow Bead: Linear porosity or cylindrical gas pockets occurring in the root bead.

Corrosion Defect:

General Corrosion: Uniform or gradually varying loss of the wall thickness over the area.

Localized Corrosion Pitting: Localized corrosion pitting can reduce the wall thickness to be less than the design thickness.

Stress Corrosion Crack: There are two kinds of stress corrosion cracking: sulphide stress corrosion cracking and hydrogen induced cracking. Suphide stress corrosion cracking occurs primarily in steels at a region subjected to applied or residual tensile stresses. Hydrogen induced cracking occurs at low stresses or even in the absence of stresses or under external compressive stresses.

The above types of damage are illustrated in Figures 3.1 and Figure 3.2.

3.2 Reference Sources

The following lists of reference sources were identified:

General Design Codes and Standards:

- Pipeline Transportation System for Liquid Hydrocarbons and other Liquids, ASME B31.4, 1998, US
- Gas Transmission and Distribution Piping Systems, ASME B31.8, 1995, US
- Code of Practice for Pipelines, BSI 8010, Part3, 1993, UK
- Oil and Gas Pipeline Systems, CAS-Z662-99, 1999, Canada
- Rules for Submarine Pipeline Systems, DnV 1996, 1996, Norway
- Rules for Subsea Pipelines and Risers, GL 1995, Germany
- Pipeline Transportation System for the Petroleum and Natural Gas Industries, ISO 13623, 1996
- Design of Long Distance Transmission Pipelines, SniP2.05.06-85, 1985,
 Russian

Codes and Standards on Pipeline Defect Assessment:

- Welding of Pipelines and Related Facilities, API 1104, 1994, US
- Pipeline Maintenance Welding Practices, API 1107, 1991, US
- Manual for Determining the Remaining Strength of Corroded Pipelines, ASME B31G, 1991, US
- Guide on Methods for Assessing the Acceptability of Flaws in Structures, BS 7910, 1999, UK
- Specification for Welding of Steel Pipelines on Land and Offshore, BS 4515, 1996, UK
- Assessment of the Integrity of Structures Containing Defects, R/H/R6 Revision 3, 1997, Nuclear Electric, UK
- Oil and Gas Pipeline Systems, CSA-Z662-99, 1999, Canada

The Specification and standards of the following organisations appear in the above codes and standards.

API American Petroleum Institute, USA

ASME American Society of Mechanical Engineers, USA

BSI British Standards Institute, UK

CEGB Central Electricity Generating Board, UK

CSA Canadian Standards Association, Canada

GL Germanischer Lloyd, Germany

ISO International Standards Organisation

The majority of sources concerning offshore pipeline defect assessment are the specific conferences and seminars. The following conferences and seminars are covered in the literature database.

- Offshore Technology Conference, API, 1985 1999
- International Pipeline Conference, ASME, 1996, 1998
- International Conference on Offshore Mechanics and Arctic Engineering, ASME, 1990 – 1998
- International Pressure Vessel Technology Conference, ASME 1990-1998
- Pressure and Piping Conference, ASME 1990 –1998
- International Offshore and Polar Engineering Conference, ISOPE, 1997, 1998
- API Pipeline Conference, API, 1990-1998
- Pipeline Engineering Symposium, ASME, 1985-1990
- Pipeline Engineering, ASME, 1991-1995
- International Conference on Pipeline Protection, MEP, 1991-1997
- Advances in Subsea Pipeline Engineering, ASPECT, 1994
- International Workshop on Offshore Pipeline Safety, MMS, 1991
- Pipeline Crossing, ASCE, 1996
- Deepwater Pipeline Technology Conference and Exhibition, Clarion, 1997-1999

In addition, the following Journals were sourced.

- International Journal of Pressure Vessels and Piping, ASME
- Oil And Gas Journal, OGJ

- Civil engineering, ASCE
- Welding Journal, AWS
- World Oil, Gulf

Several technical reports from government and companies such MMS, BP, EXXON, API are also reviewed.

To illustrate how the reference source database has been used to identify information on available data, Tables 3.1 to 3.6 provide extracts of information obtained from those references which contain data for different defect damage types. It can be observed that there is a significant number of references which contain data particularly for corrosion damage. It should be noted that further data may be identified from references still being sourced.

Ref No.	Author	Main Topic.	General Description
296	Chouchaoui and Pick	Interaction of Corrosion Pits	Describes results of experimental and finite element studies on burst strength of pipes with multiple corrosion pits
297	Chouchaoui and Pick	Corrosion assessment procedures	Proposes a comprehensive 3 level corrosion procedure drawn from series of burst tests on pipe sections with both service and simulated corrosion and a complementary series of FE analyses.
222	Roberts and Picks	Longitudinal stress assessment of corroded line pipe	Most techniques consider only the circumferential stress in the pipe in predicting the burst pressure of corroded pipe. Tests on experimental pipe sections and FE analyses to investigate longitudinal stress are assessed.
223	Wang, Smith, Popelar and Maple	Assessment procedure for corrosion under combined loading	Full scale tests of 48 inch diameter corroded pipe with FE data under combination of bending and other secondary loads.
140	Smith and Grigory	Assessment procedure of corrosion under combined loading	Full scale, small scale and FE studies on corroded pipes subjected to combined loading.
141	Cronin, Roberts and Pick	Assessment procedure for long corrosion grooves in pipes	Measured burst pipe tests with various corrosion geometries compared with FE analyses for long corrosion grooves.
313	Bubenik	Corrosion under combing loading	Combination of linear and non-linear FE studies supported by experiments under internal pressure and axial loading.
307	Stewart, Klever and Ritchie	Burst strength intact and corroded pipes	Validation of model against limited set of burst tests on uncorroded and corroded pipes.
302	Kanninen, Grigory et al.	Corrosion assessment procedure under combined loading	Validation of FE data against existing experimental data.
337	Hopkins and Jones	General corrosion assessments	Extensive full scale burst test experimental study into the behaviour of long and complex shaped corrosion and interacting corrosion. Results compared with other data.

4. OVERVIEW OF CODES/PRACTICES

4.1 General

The development of pipeline standards started in the US in the 1930's with the issue of the first B31 Code. Pipelines at that time were exclusively onshore pipelines. Later updating has resulted in a separation into a number of codes, in particular B31.4 for transportation of hydrocarbon liquids and B31.8 for transportation of natural gas. Amendments to cover offshore pipelines have been developed and issued. The ASME B31.4 and B31.8 codes, together with API 5L and the API 1104 specification for line pipe and pipeline welding, respectively, have been used and referenced by the petroleum and natural gas industries worldwide.

However, the development of significant hydrocarbon reserves in Europe and other parts of the world since the sixties has lead to diversity of pipeline standards and specifications on a national or company level. Many industrialised countries developed their own pipeline standards including the prevailing requirements of their own experts and approving authorities. Thus significant differences in safety and technical requirements for pipelines developed between the various national codes. On company level a similar process took place. This resulted in an increasing volume of standards and specifications with differences in their requirements not always relevant for the final product.

In recognition of this, the Technical Committee 67 of ISO (ISO/TC 67) was set up with the objective to develop truly international standards for the petroleum and natural gas industries. In parallel to the ISO work, Norway decided to establish the NORSOK organisation with the objective to establish common industry standards. Similar initiatives have been seen in other countries.

In particular one operator which is a strongly supporting the ISO work is STATOIL, because of its position as operator of the largest gas transmission system in the world. Secondly Statoil has clearly seen the consequences of different pipeline standards between neighbouring countries (i.e. Gas transport pipelines like Zeepipe 1, Europipe I and NorFRa cross different national sectors along their routes from the North Sea to continental Europe. National pipeline regulations and industry standards apply within the sectors resulting in, for example, varying wall thickness for the same pipeline from one sector to the next. Thirdly, pipeline technology has improved over the years resulting in improved fabrication tolerances, and better welding and NDT techniques. Furthermore, improved knowledge of pressure behaviour, external loads, corrosion protection and operational aspects have also taken place.

Offshore pipeline system can be grouped into two categories based upon their usage, oil industry pipeline systems and gas industry pipeline systems. The design, installation, inspection, repair and maintenance of offshore pipelines are covered by a number of national codes and standards, which include the following:

Pipeline Transportation System for Liquid Hydrocarbons and other Liquids, ASME B31.4, 1998, US

- Gas Transmission and Distribution Piping Systems, ASME B31.8, 1995, US
- Code of Practice for Pipelines, BSI 8010, Part3, 1993, UK
- Oil and Gas Pipeline systems, CAS-Z662-99, 1999, Canada
- Rules for Submarine Pipeline Systems, DNV 1996, 1996, Norway
- Rules for Subsea Pipelines and Risers, GL 1995, Germany
- Pipeline Transportation System for the Petroleum and Natural Gas Industries, ISO 13623, 1995
- Design of Long Distance Transmission Pipelines, SniP2.05.06-85, 1985, Russian

These codes and standards specify minimum requirements for the design, fabrication, installation, operation, re-qualification and abandonment of offshore pipeline systems. They serve, as guidelines for designers, clients, contractors and others not directly involved in the certification process. These codes and standards are not design handbooks, and the exercise of competent engineering judgement is a necessary requirement to be employed concurrently with their use.

To design an offshore pipeline system, hydraulic, mechanical and structural design manuals, even textbooks, are required besides the above mentioned codes and standards. The design process of offshore pipeline system is typified in Figure 4.1. The required design checks are also typified as shown in Figure 4.2.

4.2 **Probabilistic Design Methods**

A pipeline shall fulfill two basic functional requirements: the individual probabilities of excessive deformations, resulting in an unserviceable line, and burst, resulting in loss of contents, must be sufficiently low. The probabilities of excessive deformations and burst can be assessed using reliability analysis. There are generally three levels of such analysis at which structural safety may be treated.

Level 1. A semi-probabilistic design process in which the probabilistic aspects are treated specifically in defining partial safety factors to be applied to characteristic value of loads and structural resistances. A level 1 structural design is what is now commonly called a limit state design. It is used as a practical method of incorporating reliability methods in the normal design process.

Level 2. A probabilistic design process with some approximation. In this process, the loads and the strengths of materials and section are represented by their known or postulated distributions (defined in terms of relative parameters such as type, mean, and standard deviation) and some reliability level is accepted. Level 2 methods are not necessary for component designs (handled by level 1 limit state design) but are valuable for economic planning, monitoring, and maintenance decision-making and structural integrity evaluations.

Level 3. A design process based upon full probabilistic analysis for the entire structural system. Level 3 methods, which take into account joint probabilistic distributions of load and strength parameters and uncertainties in the analysis, are extremely complex and limited in practicality. They are used in special circumstances where the environment is particularly sensitive or where cost savings justify the additional expense of complex analysis.

Situations where probabilistic methods might be used include the determination of the factored resistance of new systems and materials and the levels of safety to control new hazards.

4.3 Reliability-Based Calibration

Any design code provides a certain safety margin against failure in design. This inherent safety margin is mainly related to the choice of safety factors sometimes selected on a more or less arbitrary basis. This has caused different safety levels for different design checks.

Limit state design implies that the performance of the pipelines is described in terms of a set of limit states for which adequate safety margins are quantified. For the entire limit states, a set of safety factors are calibrated for each safety class using a structural reliability approach. It introduces flexibility in specific conditions and provides design with a consistent safety level without compromising the safety objective. However, in a sound calibration process a varying degree of conservatism need to be introduced for individual design scenarios depending on the knowledge of the prevailing loads, pipe capacities, etc. Thus, the calibrated design criteria being generally applicable may be expected to be conservative on average.

4.4 Design Criteria and Methods in Codes

4.4.1 ASME B31.4 1998 and B31.8 1995

ASME B31.4 and ASME B31.8, together with the API 5L and API 1104 specifications for line pipe and pipeline welding, respectively, are the most widely applied pipeline codes for the Petroleum and Natural Gas Industries.

The Codes are based on traditional allowable stress design methods. The design factor for general route pipelines is 0.72 for liquid pipelines based on nominal wall thickness. In setting the design factor, due consideration has been given to and allowance has been made for the under-thickness tolerance and maximum allowable depth of imperfections provided for in the specification approved by the code.

For the gas transmission and distribution piping systems, the code specifies a Location Class as follows:

Location Class 1 is any I mile section that has 10 or fewer buildings intended for human occupancy. Location Class 1 is intended to reflect areas such as wasteland, desert, mountains, grazing land, farmland, and sparsely populated areas.

- Location Class 2 is any 1-mile section that has more than 10 but fewer than 46 buildings intended for human occupancy. Location Class 2 is intended to reflect areas where the degree of population is intermediate between location Class 1 and Location Class 3 such as fringe areas around cities and towns, industrial areas, ranch or country estates.
- Location Class 3 is any 1 mile section that has 46 or more buildings intended for human occupancy except when a location Class 4 prevails. Location Class 3 is intended to reflect areas such as suburban housing developments, shopping centers, residential areas, industrial areas.
- Location Class 4 includes areas where multistory buildings are prevalent, and where traffic is heavy or dense and where there may be numerous other utilities underground. Multi-storey means 4 or more floors above ground, including the first or ground floors.

Allowable tensile and compressive stress values for materials used in structural supports and restraints shall not exceed 66% of the specified minimum yield strength. Allowable stress values in shear and bearing shall not exceed 45% and 90% of the specified minimum yield strength, respectively.

4.4.2 BS 8010

The code takes the allowable stress design method as the basic design method as in other codes. The design factors, appropriate to the assessment of allowable stress, are given below in Table 4.1.

Hoop stress		resu func envir	Equivalent Stress resulting from functional and environmental or accidental loads		Equivalent stresses arising from construction or hydrotest loads	
Riser	Seabed	Riser	Seabed	Riser	Seabed	
0.6	0.72	0.72	0.96	1.0	1.0	

Table 4.1: Design factors f_a

Alternatively, the code allows that the acceptability of construction loads may be assessed on an allowable strain basis. The limit on equivalent stress may be replaced by a limit on allowable strain, provided that all the following conditions are met:

- Under the maximum operating temperature and pressure, the plastic component of the equivalent strain does not exceed 0.001. The reference state for zero strain is the as-built state.
- Any plastic deformation occurs only when the pipeline is first raised to its maximum operating pressure and temperature, but not during subsequence cycles of depressurization, reduction in temperature to the minimum operating temperature.

- The D/t ratio does not exceed 60.
- Welds have adequate ductility to accept plastic deformation.
- Plastic deformation reduces pipeline flexural rigidity; this effect may reduce resistance to upheaval buckling and should be checked if upheaval buckling might occur.

This approach is only permissible where geometric considerations limit the maximum strain to which the pipeline can be subjected and where the controlled strain is not of a cyclic or repeated nature.

4.4.3 DNV 1996

The DNV Rules for Submarine Pipeline Systems were first issued in 1976 and have since been updated in 1981 and most recently in 1996. It has as one of the basic objectives to "Provide an internationally acceptable standard of safety with respect to strength and performance by defining minimum requirements for the design, material selection, fabrication, installation, commissioning, operation, maintenance, re-qualification and abandonment of submarine pipeline systems.

In DNV '96 limit state design principles are adopted but allows, as an alternative, probabilistic design provided an acceptable reliability method is applied by competent personnel. The design format of the DNV 96 Rules is called a Load and Resistance Factor Design LRFD except for the requirement for pressure containment which is given in the traditional Allowable Stress Design (ASD) format.

The principle of the LRFD design format is to ensure that the level of structural safety is satisfactory such that the effect of the design load on the pipeline does not exceed the design resistance of the pipeline.

The acceptable target failure probabilities should be in compliance with the implied safety in the rules. By performing a reliability analysis for a specific design case or for a more restrictive scope of scenarios the inherent conservatism may be reduced.

In DNV '96, a novel safety class concept is introduced. Based on the fluid category, location class and phase, the pipeline is classified into a safety class. See Tables 4.2 to 4.4.

Category	Description	
Α.	Typical non-flammable water-based fluids.	
В.	Flammable and/or toxic substances which are liquids at ambient temperature and atmospheric pressure conditions. Typical examples would be oil, petroleum products, toxic liquids and other liquids which could have an adverse effect on the environment if released.	
C.	Non-flammable substances which are gases at ambient temperature and atmospheric pressure conditions. Typical examples would be nitrogen, carbon dioxide, argon and air.	
D.	Non-toxic, single-phase gas which is mainly methane.	
E.	Flammable and toxic substances which are gases at ambient temperature and atmospheric pressure conditions and which are conveyed as gases or liquids. Typical examples would be hydrogen, methane (not otherwise covered under category D), ethane, ethylene, propane, butane, liquefied petroleum gas, natural gas liquids, ammonia, and chlorine.	

Table 4.2: Categorisation of Fluids

Location Class	Description
1	The zone where no frequent human activity is anticipated along the Pipeline route
2	The part of the Pipeline/Riser in the near platform (manned) zone or in areas with frequent human activity. The extent of zone 2 should be based on appropriate risk analyses. If no such analyses are performed a minimum distance of 500 m could be adopted.

Table 4.3: Definitions of Location Classes

Phase	Fluid Category A and C Location Class		Fluid Category B, D and E Location Class	
	1	2	1	2
Temporary	Low	Low	Low	Low
Operational	Low	Low	Normal	High

Table 4.4: Normal Classification of Safety Classes

Determination of appropriate target safety levels is fundamental to the process of developing new design criteria through the application of reliability methods. A target safety level is defined as the maximum acceptable failure probability level for a particular limit state design to be accepted, see Table 4.5 below:

Limit State	Probability		Safety Classes		
Category	Bases Lov		Normal	High	
Serviceability	Annual per Pipeline ¹⁾	10-2	10 ⁻³	10 ⁻³	
Ultimate	Annual per Pipeline ¹⁾	10-3	10-4	10 ⁻⁵	
Fatigue	Lifetime probability per Pipeline ²⁾	10 ⁻³	10-4	10 ⁻⁵	
Accidental	Annual per km³)	10-4	10-5	10 ⁻⁶	

- 1 Or the length of the period in the temporary phase
- No inspection and repair is assumed, temporary and in-service conditions considered together
- Refers to the overall allowable probability of severe consequences.

Table 4.5: Recommended Target Safety Levels

The evaluation of the target safety level for pipelines should primarily be based on the implied safety in currently accepted design practice, using uncertainty measures representative at the time when the code was made. Further, the nature of failure and the actual consequence potential in terms of hazard to human health and safety, damage to the environment, economic losses, and the amount of expense and effort required to reduce such hazard potential should be take into account.

With no implicit safety level available, the rules provide recommendations on target failure probabilities versus safety class and limit state category. The base for the values of safety factor rely on a conservative assessment of implied safety in current accepted design practice guided by accident statistics and engineering judgement.

Limit State Categories:

Typical Limit States and corresponding limit state categories for a pipeline may be:

Serviceability/Limit State (SLS) Category

Ovality / ratcheting Limit State

- Accumulated plastic strain Limit State
- Damage due to or loss of weight coating
- Yielding

Ultimate Limit Sate (ULS) Category

- Bursting Limit State
- Local buckling Limit State (pipe wall Limit State)
- Global buckling Limit State(normally for load-controlled condition)
- Unstable fracture and plastic collapse Limit State

Fatigue Limit State (FLS)

Fatigue due to cyclic loading

Accidental Limit State (ALS) Category

- Dropped objects
- Trawl gear hooking
- Earthquake.

The hoop stress formula in the DNV rules is the same as in the ISO standard. The design factor requirements for pressure containment is, however, formulated as a dual requirement, namely as a check against yielding and a check against bursting as shown in Table 4.6

Safety Class	Low	Normal	High
Yielding	0.83	0.77	0.77
Bursting	0.72	0.67	0.64

Table 4.6: DNV 96 Hoop Stress Design Factors

A further possibility to benefit the designer is in the application of high quality material. The design factors given in Table 4.7 below apply when specified material quality requirements are satisfied.

Safety Class	Low	Normal	High
Yielding	0.85	0.80	0.80
Bursting	0.74	0.70	0.67

Table 4.7: DNV 96 Hoop Stress Design Factors, best material

Differences can be noted when comparing DNV with ISO as follows:

- The design requirements of ISO are based on yielding exclusively, whilst DNV applies both yielding and bursting as actual failure modes and presents a dual requirement for both.
- The design factors specified by DNV for yielding are generally the same as the ones specified by ISO. Whilst the factors in ISO basically rest on ASME B31.4/B31.8 and long term industry practice, the design factors in DNV are supported by extensive research programmes.
- The design factors in ISO are specified depending on fluid category and location, whilst those of DNV 96 are given by safety Class and in spite of the fact that the two standards generally specify the same design factors for the yielding criterion, the two design formats are basically different and may give different results in some cases

4.4.4 <u>CSA Z662- 1999</u>

In the code CSA Z662-99, allowable stress design is still used for the design criteria. The stress design requirements are considered to be adequate under conditions usually encountered and for general stress design of conventional pipeline systems. The design factors are given in Table 4.8

	Load condition		
System	A	В	Pressure Testing
Pipelines	0.72	1.00	1.00
Risers	0.60	0.80	1.00

Table 4.8: Design Factors

As an alternative, it permits for oil and gas pipelines to be designed in accordance with the requirement of limit state design methods given in Appendix C of the code as illustrated in Figure 4.3, provided that the designer is satisfied that such designs are suitable for the conditions to which such pipelines are to be subjected.

Class Location:

- Class 1: Class location assessment areas that contain 10 or fewer dwelling units shall be designated Class 1 location
- Class 2: class location assessment areas that contain more than 10 but fewer than 46 dwelling units shall be designated Class 2
- Class 3: Class location assessment areas that contain 46 or more dwelling units shall be designated Class3 location

 Class 4: Class location assessment areas where buildings intended for human occupancy with 4 or more storeys above ground are prevalent shall be designated Class 4 location.

Limit State Categories:

Ultimate Limit States

- Rupture
- Yielding caused b primary loads
- Buckling resulting in collapse or rupture
- Fatigue
- Serviceability limit states
- Yielding caused by secondary loads
- Buckling not resulting in Collapse.

4.4.5 ISO/DIS 13623-1996

The standard uses maximum permissible stresses as the basic concept for ensuring pipeline integrity and serviceability. Formulas and design factors are given for hoop stress and equivalent stress. Strain based design is allowed in specific cases.

The use of the reliability based limit state design method may be applied with one important exception, namely that of design for pressure containment for the general route part of the pipeline.

The hoop stress formula of the ISO standard is based on the average between inner and outer diameter of the pipeline and on minimum wall thickness as shown in Figure 4.4. This is different from the traditional formulation (i.e. ASME) which is based on nominal outer-diameter and nominal wall thickness. The traditional formulation was established for thin wall pipelines, whilst modern offshore gas trunklines are designed to much higher pressures giving thicker walls.

The formulation in European standards varies between the countries. Statoil for example has used a formulation based on inner diameter and minimum wall thickness. The result of the different formulations is that different standards in reality express different levels of steel utilisation for pressure containment in spite of the fact that they all prescribe the same design (ie. utilisation factor of 72% of yield strength).

Another effect inherent in the traditional design formulation for pressure containment is that the real steel strength utilisation expressed by the formulation is different when applied to pipelines with highly different design pressures. Thus the requirement works differently for an onshore gas pipeline with a design pressure

typically in the range 60-80 bars and a flowline with a design pressure of say 400 bars both fabricated with the same wall thickness tolerances (eg. API 8%).

The practical consequences are such that the requirement for pressure containment normally determines the wall thickness of the pipeline steel. Therefore for the above example this would mean that the flowline would need relatively more steel than an onshore gas line in order to meet the same requirements when using the traditional formulation.

The hoop stress factors were calibrated to lead to the same wall thickness as required in ASME B31.4 and B31.8 for an average pipeline with a D/T of 60 and a 8% wall thickness tolerance. These factors are given in Table 4.9 below:

Location	Design factor u
General Route*	0.77
Shipping Lanes, designated anchoring areas and harbour entrances	0.77
Landfalls	0.67
Pig traps and multipipe slug catchers	0.67
Risers and station piping	0.67

^{*} The factor may be increased to 0.83 for pipelines conveying category C and D fluids

Table 4.9: ISO Hoop stress design factors for offshore pipelines

5. DEFECT ASSESSMENT METHODS IN CODES

5.1 Assessment of Weld Defects

5.1.1 API 1104

This standard cover the gas and arc welding of butt, fillet, and socket welds in carbon and low alloy steel piping used in the compression, pumping, and transmission of crude petroleum products and fuel gases and, where applicable, covers welding on distribution systems. This standard also covers the acceptance standards to be applied to production welds tested to destruction or inspected by radiography. It includes the procedure for radiographic inspection.

The standard presents the acceptance standards for nondestructive testing, which apply to discontinuities located by radiographic, magnetic particle, liquid penetrant, and ultrasonic test methods. These acceptance standards are based on empirical criteria for workmanship and place primary importance on flaw length. Such criteria have provided an excellent record of reliability in pipeline service for many years.

In addition, API 1104 allow the use of alternative fitness-for-purpose criteria based on fracture mechanics analysis, which incorporates evaluation of the significance of both flaw depth and flaw length. The fit-for-purpose criteria provide more generous allowable flaw sizes, but only when additional procedure qualification tests, stress analysis, and inspections are performed.

The method requires that the welding procedures are qualified for either of two minimum CTOD toughness levels: 0.005 inch or 0.010 inch. Then, for a given maximum applied strain, the allowable defect depth is inferred. Limits on defect length are dependent on defect depth.

A residual strain of 0.2% has been included in developing the acceptance criteria in order to account for postulated residual stresses of yield magnitude. Defect depth may be determined by NDT techniques or by consideration of inherent size limitations due to weld pass geometry.

5.1.2 BS 7910

As the replacement of PD 6493 and PD 6539, this code outlines methods for assessing the acceptability of flaws in all types of structures and components. Although emphasis is placed on welded fabrications in ferritic and austenitic steels and aluminium alloys, the procedures developed can be used for analysing flaws in other materials and in non welded applications.

The fracture assessment procedures described in this guide are a development of the 1991 edition of PD 6493. Although there are continuing advances and improvements in fracture assessment methods, the procedures presented are felt to represent approaches which have been validated extensively and are intended to provide consistently accurate and safe predictions. They combine the Crack Tip Opening Displacement Methods introduced by the Welding Institute via the 1980 edition of

PD6493 with approaches based on the R6 procedures published by Nuclear Electric/Magnox Electric (formerly Central Electricity Generating Board).

The code contains improvements to the approaches in PD6493:1991 based on user experience, additional solutions and improved guidance from various literature sources, and a fuller integration of R6 Rev 3 procedures.

As in the 1991 edition of PD 6493, three levels of fracture assessment are available to the user. The choice of level depends on the input data available, the level of conservatism and the degree of complexity required.

Level I: this is the screening level introduced into the 1991 version of PD6493 and broadly compatible with the 1980 edition of the document. This level provides a conservative estimate from its use of the simplified FAD with in built safety factors and required conservative estimates of the applied stress, residual stress and fracture toughness.

Level II: this is considered to be the normal assessment route applicable for general structural steel application and makes use of a more accurate FAD with no inherent safety factors. The procedure permits the prediction of acceptability of the structure when all three input parameters are known and also allow limiting values of any one parameter to be predicted.

Level III: This level employs a full tearing instability approach and therefore provides a more accurate description of the performance of ductile materials.

All levels refer to tensile Mode I failure only. Shear failure is dealt with the method in Annex B. All three levels of assessment use a Failure Assessment Diagram (FAD) which combines consideration of fracture and local plastic collapse.

5.1.3 CSA Z662-99

Work quality standards of acceptability have been based on experience with traditional welding and inspection practices. This experience has indicated the capabilities of welding procedures and personnel in minimizing the incidence of welding imperfections during production welding of pipe girth welds.

Appendix J is to outline the application of the concept of engineering critical assessment to fusion welds. Standards of acceptability based on ECA include consideration of the measured weld properties and intended service conditions for a specific application. Alternatives to the work quality standards of acceptability can be derived for sections of a new pipeline.

Appendix K provides the analytical methods that shall be used to derive standards of acceptability for weld imperfections, which may be used as an alternative to the standards. The standards of acceptability that are derived are based on engineering critical assessment and include consideration of the measured weld properties and the intended service conditions.

5.1.4 R/H/R6 Revision 3

R/H/R6 was originally published as a CEGB Report entitled "Assessment of the Integrity of Structures Containing Defects" 1976.

The R6 defect assessment procedure uses the concept of a failure assessment diagram (FAD) to define the boundary between the safe and unsafe operating conditions of the flawed structures.

The procedure described in the main document adopts a deterministic approach in which specific combinations of defect size and material property values are chosen to ensure a conservative result in the assessment of defect structures. The elastic-plastic assessment procedure used in the R6 approach can form the basis of a probabilistic assessment procedure where the uncertainties in the main assessment parameters are included. In appendix 10, a probabilistic assessment procedure based on the R6 analysis is described which takes account of developments in probabilistic fracture mechanics in recent years. This extends previous applications of probabilistic fracture mechanics, which have been based mainly on linear elastic fracture mechanics, to elastic-plastic fracture analysis more appropriate for the assessment of general engineering structures.

5.2 Corrosion Defect Assessment

5.2.1 ASME B31G

This is a supplement to ASME B31 code for pressure piping. It provides a semiempirical procedure for the assessment of corroded pipes. The procedure was developed in the late sixties and early seventies at Battelle Memorial Institute.

Based on an extensive series of full-scale tests on corroded pipe sections, it was concluded that the experiments on corroded pipe indicated that line pipe steels have adequate toughness and that the toughness is not a significant factor. The failure of blunt corrosion flaws is controlled by their size and the flow stresses or yield stresses of the materials.

Limitations on the use of the B31G procedure include:

- 1. It applies to corrosion defects only in the body of the pipe which have relatively smooth contours and cause low stress concentration
- 2. It applies to pipes under internal pressure loading only.

The assessment procedure considers the maximum depth and longitudinal extent of the corroded area, but ignores the circumferential extent and the actual profile.

If the corroded region is found to be unacceptable, B31G allows the use of more rigorous analysis or a hydrostatic pressure test in order to determine the pipe remaining strength. Alternatively, a lower maximum allowable operating pressure may be imposed.

6. DATABASE

6.1 <u>Database Requirements</u>

A prime deliverable from this project is a database on the strength of pipelines containing defects. The usefulness of any database is very dependent on the care exercised during its development, particularly with such issues as completeness of captured data, quality assurance and database structure.

MSL's experience in the area of database preparation would indicate that time spent during the initial set-up (i.e. in defining the fields of the database) pays dividends during data entry, data checking and eventual use. As an example, different source documents will use different units (e.g. inches v. millimetres) whereas the data in the database needs presenting in consistent units. However, to facilitate the checking of data entry against the source documents, it is easier to use the original unit systems of those documents. The database therefore contains a degree of duplicated columns; one set based on original units and the other with consistent units. After data entry checking, the columns with original units can then be hidden for presentation purposes.

It is important to capture the data fully. For instance, the pipe thickness will normally be quoted but it may be relevant in subsequent analyses to know whether this value was nominal, measured or inferred (from other variables such as D and D/T). This information has therefore been carefully recorded. In a similar vein, the steel yield stress is preferably a measured value but may have been given in terms of the specified minimum value. Again, such information needs to be recorded, including both measured and specified values if available. The inclusion of a 'comment' field is essential for recording peculiar testing characteristics. In all cases, tabular information in the source documents is to be preferred over graphical information as the latter may introduce scaling errors when extracting data.

Consideration was given to setting up a number of separate databases according to defect type: dent, gouge, cracks, corrosion, etc. However, many of the fields would be common, e.g. fields describing pipe geometry, materials, loading, etc. It was therefore decided to generate a Master Database, subsets of which could be extracted later for subsequent appraisal. A detailed description of all fields is given in the next subsection.

6.2 **Description of Fields**

The fields defined in the Master Database are reproduced in Table 6.1. In the actual database, the field headings stretch along one horizontal line. The numbers in the first row refer to Notes given in Table 6.2.

Table 6.1: Database fields (...continued)

Notes: 1 SLI = Fully acceptable data SL2 = Acceptable data but some nominal values used SL3 = Acceptable data but peculiarities SL4 = Incomplete data, reject M = Mechanical damage (dent and/or gouge) C = CorrosionF = Fatigue crack W = Weld defect O = OtherN = NominalM = Measured C = Calculated U = UnknownSMLS = Seamless SAW = Submerged Arc Welding ERS = Electric Resistance Welding N/A = Not applicable (for FE data)Sq = Square indentor Cyl1 = Cylinder transverse to pipe Cyl2 = Cylinder longitudinal to pipe Sph + Spherical indentor O = OtherGW = Girth weldLW = Longitudinal weld P = Parent material 7 G = GeneralI = Internal E = External P = PitL = Localised

Table 6.2: Database notes

Inspection of Table 6.1 shows that the data has been entered under ten main headings, with sub-headings as follows:

i) Specimen Identification

The 'reference number' and 'author' are the same as in the list of References herein. The 'spec ID' is the specimen identification as used in the source document. The author and spec ID fields are useful in weeding out duplicate sets of data. Each specimen is given a unique 'sequence number' to facilitate traceability following screening and the creation of data subsets. Where a specimen requires multi-row entries (e.g. for the recording of crack growth data) then letters a, b, c etc. are used after the sequence number to distinguish the row entries. The 'type' column refers to whether the data are test data or finite element (FE) data. The entries under 'screening level' and 'type of defect' are defined in Notes 1 and 2 in Table 6.2 respectively. The latter will be useful for sorting the database and in preparing data subsets.

ii) Pipe Geometry

The sub-headings under this grouping are self-explanatory especially when read in conjunction with Note 3 in Table 6.2. As explained above, the 'source' columns are used for data entry purposes and can be hidden after the data has been checked.

iii) Pipe Specification

The three sub-headings under 'pipe specification' record the pipe manufacturing process and the type of material.

iv) Material Properties

Again, these sub-headings are self-explanatory.

v) Loading

The 'load type' identifies the loading regime as appropriate, e.g. pressure, axial, bending, etc. The loading range (or ranges if multi-row entries are being used for crack growth tests) is entered under the 'source' column in the original units. The 'number of cycles' is only relevant for fatigue or crack growth tests, otherwise N/A is entered.

vi) Material Parameters

Sub-headings are provided for brittle fracture parameters, Fracture Mechanics parameters and residual stresses. These parameters might be given in some source documents and will become relevant during appraisals of the various defect assessment methodologies.

vii) Mechanical Damage

The entries under this heading are to characterise the shape, size and location/orientation of dents and gouges. Once again, duplicate columns allow for data entry using source document units and then transposition to a consistent set. The first column under this heading, 'type', allows for subsequent sorting.

viii) Corrosion

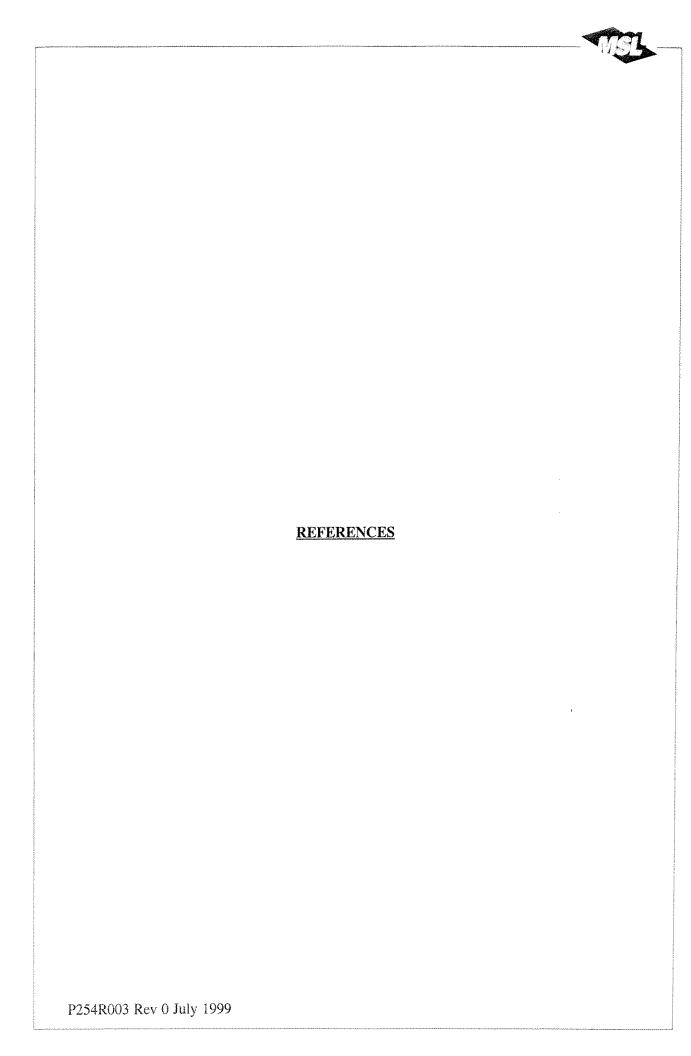

The corrosion section allows data pertaining to the nature and extent of any corrosion to be entered. The 'corrosion type' is a qualitative field and is used to define whether the corrosion is internal or external, localised or general, etc.

ix) Crack

The location, depth and length of a crack are entered here.

x) Comments

This section allows the embellishment of any noteworthy aspects gleaned from the source document. It is particularly useful for recording any peculiar testing procedure or observation that is not addressed in other fields.

Dear ^^^^

Pipeline Defect Assessment

MSL, an independent engineering consultancy, has been commissioned by the Minerals Management Service (MMS) to conduct a study on the methodologies applicable to assessing defects in pipelines. The objectives of the study are to collate available assessment approaches for pipeline defects (e.g. dents, gouges, corrosion and cracks) and to develop a database (of numerical and test data) on the strength of pipelines containing defects. The various assessment procedures can then be calibrated against the database.

Our purpose in writing to you is to explore the possibility of arranging a meeting with you, or a colleague, in the near future. It would be most helpful to our study if you could agree to a meeting. We would be particularly interested to learn about the assessment methodologies you might use for given defect scenarios. We would also be delighted to receive any test or numerical data of pipelines containing defects to enhance the database. Any such data will be de-sensitised. We appreciate that your time is valuable and therefore propose only a short meeting, say 20 minutes. We will call you shortly to see whether it would be advantageous for us to visit and, if so, to arrange a mutually convenient time.

Yours sincerely
